Abstract

In this part we study the traffic and quality characteristics of spatial scalable encoded videos. Six video sequences representing different genres were spatially encoded into two layers, the base layer, and the enhancement layer. Each sequences are of CIF type and 30 minutes in length. We studied the traffic and quality characteristics of base layer (QCIF), the enhancement layer (traffic only) and the aggregated layer (base + enhancement layer). A 12 frame GoP was chosen for base layer and enhancement layer, such that spatial layer GoP matches with that of single layer encodings. Our encodings with rate control have a rate-controlled base layer, while the corresponding layer is encoded without rate control. These encodings are well suited for simulating the widely advocated networking scenario with a nearly constant bit rate base layer and a variable bit rate enhancement layer. Our statistical analysis provides an insights into these layer streams and there behavior when compared to the corresponding single layer encodings. Our traffic studies shows a double "hump" in coefficient of variation and peak–to–mean ratio for both base layer traffic and the aggregated layer traffic. These peaks are centered at quantization parameter corresponding to 060810 and 101416. In most of the cases, the Hurst parameter estimated from the R/S plot, the periodogram, and the variance time plot are the same for the base layer traffic and the enhancement layer traffic. This indicates that long range dependence is not changed by scaling the input video sequence.

1 Introduction

In this part we conduct a statistical analysis of the video traffic and the video quality for the spatial scalable encoded video. This statistical analysis is based on the terse traces of the base

layer and the corresponding enhancement layer. Recall from Part 1 that the terse traces give the frame sizes of the individual layers. In addition, the terse base layer trace gives the qualities (PSNR values) of the luminance component of the base layer stream. The terse enhancement layer trace gives the improvement in the PSNR of the luminance component achieved by the enhancement layer.

2 Analysis of Video Traffic

In this section we analyze the frame sizes (traffic) of the spatial scalable encoded videos. We first study the statistical characteristics of the base layer traffic, then the enhancement layer traffic, and finally the correlations between base layer and enhancement layer traffic. Recall that in the considered spatial scalable encodings, each frame has a base layer component and an enhancement layer component.

2.1 Base Layer Traffic

We give the compression ratios, the mean frame sizes ($\bar{X}^b$), the coefficients of variation (CoV_X^b), and the peak-to-mean ratios ($X^b_{\max}/\bar{X}^b$) in Table 1, along with the mean bit rates ($\bar{X}^b/T$), and the peak bit rates ($X^b_{\max}/T$).

It is interesting to note that the average size of a QCIF frame encoded without scalability or rate control is roughly the same size as a spatially scalable encoded frame from the base layer of the same movie in CIF format. From Table 1 of this report, as well as from Table 1 of Part 2, we observe that the relative order of the compression ratios achieved for video sequences at a given quality level is the same for both single layer encodings and encodings with spatial scalability.

The encoder used in this study was able to achieve the 128 kbps and 256 kbps target bit rates for the spatial encoding of a sequence with rate control, just as it did for single layer encodings with rate control. For a target bit rate of 64 kbps, the spatial encoder with rate control shows variations in the achieved bit rates. The encoder was able to achieve the target bit rate of 64 kbps for the *Silence of the Lambs* video sequence for both spatial and single layer encodings, whereas for the remaining three video sequences — *Terminator I*, *Snowboard with Commercials*, and *Oprah without Commercials* — the encoder achieved higher than the target 64 kbps bit rate for both the single layer and spatial encodings of the corresponding sequences in CIF format. Additionally, for these three video sequences, the bit rates achieved for a target of 64 kbps were nearly equal and have mean bitrate greater than 64kbps for the largest quantization parameter 30,30,30 when we compare single layer encodings with spatial base layer encodings.

The coefficient of variation of a single layer encoded video sequence does not appear to have a consistent relationship with the coefficient of variation of the video sequence encoded with spatial scalability. Sometimes the CoV_X^b is larger for a spatially encoded video sequence than the single layer encoding, and sometimes the CoV_X^b is larger for a single layer encoding than the video encoded with spatial scalability, although the values for the two for encodings with and without scalability are very close to one another.

When interpreting the statistics given in various tables, keep in mind that the base layer of the studied spatial scalable encoding provides the video in the QCIF format. Single layer video in the QCIF format is studied in Part 2 of this technical report. We will therefore now compare the base layer statistics here with the single layer QCIF statistics from Part 2.

We observe that the compression ratio of the base layer video is about four times larger than the compression ratios of the single layer QCIF video in Table 1 of Part 2. This is to be expected as the QCIF format has half the number of pixels as the CIF format in both the horizontal and the vertical direction. Taking a closer look at the average base layer frame size ($\bar{X}^b$) of the encodings without rate control in comparison with the corresponding average single layer QCIF frame sizes ($\bar{X}$) in Table 1 of Part 2, we observe the following.

For the high quality encodings without rate control, the $\bar{X}^b$ values of *Terminator I*, *Snowboard with Commercials*, and *Oprah without Commercials* are between 4% and 6% larger than the $\bar{X}$ values . For the medium quality, the $\bar{X}^b$ values are between 1% and 4% larger. The $\bar{X}^b$ of the high and medium quality of *Silence of the Lambs*, on the other hand, are about the same as $\bar{X}$. For the low quality encodings of *Snowboard with comm* and *Oprah w/o comm* the $\bar{X}^b$ are between 0.5% to 2% smaller than the corresponding $\bar{X}$. For *Silence of the Lambs* and *Terminator I*, $\bar{X}^b$ is nearly 1% to 4% higher than $\bar{X}$ for various quality levels.

Next, we notice that for the encodings without rate control, the behavior of the traffic variability measured in CoV_X^b and $X_{\max}^b/\bar{X}^b$ compared to CoV_X and $X_{\max}/\bar{X}$ in Table 1 of Part 2 is complementary to the behavior of the mean frame size ($\bar{X}^b$). Specifically, while the values appear to be very close, the encodings without rate control of *Terminator I*, *Snowboard with Commercials*, and *Oprah without Commercials* have usually smaller CoV_X^b and $X_{\max}^b/\bar{X}^b$ compared to CoV_X and $X_{\max}/\bar{X}$ of the corresponding single layer QCIF encodings. For *Silence of the Lambs* we do not find a consistent behavior for non-rate controlled encodings.

For encodings with rate control we observe again that the TM5 rate control matches the target bit rates of 128 kbps and 256 kbps while having problems meeting the 64 kbps target bit rate. There appears to be no clear general trend in the behavior of the variability of the base layer encodings with rate control in comparison with the variability of the corresponding single-layer QCIF encodings. Only for the 128 kbps encodings, there is a clear trend in that

the base layer encodings have smaller CoV_X^b and $X_{\max}^b/\bar{X}^b$. For the other quality levels we observe conflicting trends in CoV_X^b and $X_{\max}^b/\bar{X}^b$. For the 256 kbps encodings for instance, CoV_X^b is smaller than CoV_X, while there is no clear trend in the behavior of $X_{\max}^b/\bar{X}^b$ with respect to $X_{\max}/\bar{X}$.

Considering the base layer traffic for the different quality levels without rate control, we observe a double "hump" behavior of first increasing and then decreasing variability as the quality level decreases. The first hump is observed at 060810 and the second hump at M.Q.

Table 2 gives the mean GoP size $\bar{Y}^b$, the coefficient of variation of the GoP sizes CoV_Y^b, and the Peak-to-Mean ratio $Y_{\max}^b/\bar{Y}^b$ of the GoP sizes, as well as the Peak bit rate $Y_{\max}^b/(GT)$ of the GoP trace.

We observe that the $Y_{\max}^b/\bar{Y}^b$ and $Y_{\max}^b/(GT)$ values for the base layer encodings without rate control are consistently smaller than the $Y_{\max}/\bar{Y}$ and $Y_{\max}/(GT)$ values in Table 2 of Part 2. On the other hand, there appears to be no clear trend in the correlation of the behavior of CoV_Y^b in comparison with the corresponding single layer CoV_Y.

For the encodings without rate control, we observe that $Y_{\max}^b/\bar{Y}^b$ is largest for medium quality (quantization parameter ranging from 101010 to 101416) than any other quality encoded video. CoV_Y^b is largest for the H.M quality level encoded videos when compared with other encodings with and without rate control. The behavior of $Y_{\max}^b/\bar{Y}^b$ and CoV_Y^b is the same as was observed earlier several times i.e., we find a "hump" where the peak is centered around the medium quality encoding. The variability of the GoP size for the medium quality traces is greater than the variability of the GoP size for both the high and low quality traces. This observation can also be made from Figure 4, which shows the GoP size histograms. The medium quality encoding of *Snowboard with Commercials* has a much wider histogram, than either of the two histogram plots of the high quality *Silence of the Lambs*, or the low quality *Oprah without Commercials*.

For the rate-controlled sequences, $Y_{\max}^b/\bar{Y}^b$ are largest for videos encoded with 64 kbps and 128 kbps target bits when compared to 256 kbps target bit rate encoded videos. However the peak-to-mean ratios do not exhibit a consistent relationship when compared for the 64 kbps and 128 kbps target bit rates. We observe that CoV_Y^b are largest for the encodings with a target bit rate of 64 kbps, followed by 128 kbps, and have the smallest values for the sequences with a target bit rate of 256 kbps. These values imply that the encodings with a target bit rate of 64 kbps have more GoP size variability than encodings with a target bit rate of 128 kbps, which in turn have more GoP size variability than encodings with a target bit rate of 256 kbps. This can also be observed in Figure 4, which, as was mentioned above, gives the GoP size histograms. While it is difficult to observe the difference in the variability of the 128

kbps and 256 kbps encodings of *Snowboard with Commercials* and *Silence of the Lambs* — they both appear to be very sharp — the 64 kbps encoding of *Oprah without Commercials* has a much duller peak than these other two histograms. Also, we observe that the 128 kbps and 256 kbps base layer encodings have typically somewhat smaller peak-to-mean ratios and peak bit rates than the corresponding single layer encodings.

The GoP level peak-to-mean ratio ($Y_{\max}/\bar{Y}$) and the coefficient of variation (CoV_Y^b) of spatially scalable encoded CIF video sequences decreases because as the aggregation level increases, the encoded frame sizes traffic becomes more smooth. We observe that for a given video, the mean GoP size of the base layer of the spatial encoding is nearly equal to the mean GoP size of the single layer encoding (QCIF).

The effect of the source video quality can have a severe impact on the compression ratios as is observed with *LectureHQ-Reisslein*. The poorer the source sequence video quality, the smaller the compression ratio achieved for the same quality encoding. This ratio can vary from 3 for high quality encoding to nearly 2 for low quality encoding. This is due to the fact that the existing compression algorithms try to exploit the high degree of correlation in neighboring pixels. Noisy video sequences tend to have small correlation of neighboring pixels, thus severely effecting the compression ratios. The coefficient of variation is smaller for the base layer of the spatial encoded video when compared with the single layer encoded video (QCIF). However, we do not observe any consistent trend in peak-to-mean ratios. The peak bit rates of spatially encoded CIF video sequences are smaller than the peak bit rates of the single layer encodings of QCIF video sequences. This difference can range anywhere from zero to around 600 kbps.

The CoV_X^b decreases for all spatially encoded CIF video sequences at the target bit rates of 128 kbps and 256 kbps when compared to the single layer encoded QCIF video sequences. For other encoding modes, the CoV_X^b has no consistent relation between single layer and spatial scalable encodings. The peak-to-mean ratio is smaller in the spatial encodings than for the single layer encodings at the GoP level for almost all video sequences as well as for all the encoding modes.

Figure 1 gives frame sizes X_n^b (in bytes) as a function of the frame number n. We observe from these plots that the encodings without rate control generate highly variable frame sizes that are characteristic of open-loop video encodings. The encodings with rate control appear generally less variable. However, there are occasionally very large spikes in the frame sizes, which appear to be the reason for the relatively large CoV_X^b and $X_{\max}^b/\bar{X}^b$ observed in Table 1.

Figure 2 gives the GoP size Y_m^b (in bytes) as a function of the GoP number m. From Figure 2 we observe the variability of the GoP sizes that we described above.

Figure 3 gives the histograms of the frame sizes X_n^b. The histograms of the base layer frame sizes look fairly similar to the QCIF single layer frame size histograms in Figure 3 of Part 2, except for the absence of the second "bump" at large frame sizes in most of the base layer histograms.

The effectiveness of the rate control scheme employed in this investigation can be observed from the histogram plots shown in Figure 3. As the target bit rate increases from 64 kbps to 256 kbps, the histograms become narrower, and the peaks become sharper indicating that more frames are concentrated in a small range around the target bit rate. This range decreases as the target bit rate increases. This shows that as the target bit rate increases CoV_X^b decreases, as we have already observed. An ideal rate-controlled sequence would have a frame size histogram plot represented by an impulse at the target average frame size, which can be derived from desired target bit rate. From these histogram plots we observe that the high quality encoding of *Silence of the Lambs* has a broad distribution as well as a longer distribution tail than the low quality encoding of *Oprah without Commercials*, which has a narrower frame distribution and a shorter distribution tail.

It is interesting to note that *Oprah without Commercials* has different frame size distributions. All of the plots have multiple peaks meaning that the frame sizes are concentrated into multiple set of predominant ranges. This distinct set of frame sizes are clearly visible from the GoP size trace plots in Figure 2. The *Oprah without Commercials* GoP size plot shows a large number of rectangular regions, which look like small rectangular wells in the plot, and which correspond to a roughly constant frame size. This leads to multiple peaks in the histogram plot. The same phenomenon is observed in the histogram and frame size trace plots of the single layer encoding of *Lecture–Reisslein*. This behavior appears to be due to the video content, where both sequences have something in common i.e., in both there are only infrequent scene changes unlike in sports or commercials films.

Figure 5 gives the autocorrelation coefficient $\rho_X^b(k)$ of the frame size sequence X_n^b, $n = 0, \ldots, N-1$, as a function of the lag k (in frames). The large peaks, spaced 12 frames apart in these autocorrelation functions, are again due to the I-I/P-P correlations discussed in Part

1. The smaller peaks spaced 3 frames apart are due to the I-P/P-P frame size correlations. For the low quality and 64 kbps target bit rate these smaller peaks are not present. This is because the P and B frames tend to have the same sizes in these encodings.

The peaks in Figure 5 correspond to the large I frame sizes which are separated by a 12 frame period lag in the base layer. The autocorrelation function slope tends to be constant (roughly zero) for rate controlled video encoded sequences. This is because of nearly constant frame sizes in base layer. For our encodings rate control in applied only for base layer, enhancement layer for our encodings is non-rate controlled.

Figure 6 gives the autocorrelation coefficient $\rho_{Y^b}(k)$ of the GoP size sequence $Y^b_m,\ m = 0, \ldots, N/G - 1$, as a function of the lag k (in GoPs). Remarkable is the large autocorrelation between 0.4 and 0.5 for lags up to 100 GoPs of the high quality *Silence of the Lambs* base layer. The autocorrelation coefficient for the base layer frame size trace at the GoP level decreases sharply for video sequences encoded at target bit rates of 256 kbps and 128 kbps. The autocorrelation drops to zero for lags of 20 GoPs. However, it takes lag periods of around 80 GoPs to bring the autocorrelation to nearly zero for target bit rate of 64 kbps. We find random fluctuations in the GoP level autocorrelation function for all rate controlled encoded sequences which is not observed in non-rate controlled encoded sequences. The same phenomenon was observed in single layer encoded sequences.

Table 3 gives the Hurst parameter determined with the R/S method (the first line of the given video and encoding mode) and the periodogram (the second line of the given video and encoding mode) for $X^b_n,\ n = 0, \ldots, N - 1$, as a function of the aggregation level a.

Table 3: Hurst parameters estimated from pox diagram of R/S and periodogram as a function of the aggregation level a for base layer traffic.

Long range dependence is measured in terms of the Hurst parameter (H), which lies in the range of $0.5 \leq H \leq 1$. A Hurst parameter value of 0.5 means that the sequence does not have long range dependence; a value of $0.5 < H < 0.75$ indicates weak long range dependence and a value of $0.75 < H \leq 1$ indicates strong long range dependence. Generally speaking, a larger H means stronger long range dependence. Estimates of long range dependence are more accurate when taken at higher aggregation levels a, typically $a > 192$. Thus, any comparisons that are made with the Hurst parameter need to be made with estimates at aggregation levels $a > 192$. See [1] and [2] for more information about the Hurst parameter.

The long range dependence behavior is same as was found in the single layer encoded video sequences discussed in Part2 of the technical report series. From Table 3 we observe that, as the aggregation level increases for a given quality level, the H estimates tend to oscillate. We further observe that the H estimates of a video trace for different quality levels do not show a consistent behavior. Some show decreasing H estimates as the quality decreases (*Silence of the Lambs*), whereas others show a oscillatory behavior. However, we observe that as the quality level changes, there is a small change in H estimate and practically this change is negligible concluding that long range dependence cannot be changed by changing the quality level of encodings; it rather appears to be a property of the source video sequence. Of all the sequences, *ParkingLot* is the only sequence which does not exhibit long range dependence (H estimate is around 0.5). This can also be concluded from the nearly exponential decay of the autocorrelation plot of the frame sizes. *Snowboard with Comm* exhibits a weak long range dependence with $H = 0.6$ as frame size autocorrelation plots show a nearly exponential decay.

For rate control encodings, we conclude that there is no long range dependence for target bit rates of 128 kbps and 256 kbps as $H < 0.5$ in most of the cases. For a target bit rate of 64 kbps some video sequences exhibits a weak long range dependence (*Oprah w/o Comm*), some show a strong long range dependence (*Silence of the Lambs*), others show no long range dependence (*LectureHQ-Reisslein*).

Table 4 gives the Hurst parameter estimated using the variance time plot as well as the scaling parameters $\underline{c}_f$ and α (also expressed as $H = (1 + \alpha)/2$) estimated from the logscale diagram. Figures 7, 8, and 9 give the variance-time plots, the pox plots of R/S (for $a = 12$), and the periodogram (for $a = 12$). It is observed that the H estimates from the variance time plots are very close to the H estimates given by the R/S plots at the aggregation level of $a = 192$ for encodings without rate control. Hurst parameter estimate from the periodogram technique tends to give a higher H value than the corresponding H obtained using the R/S estimate or the variance time analysis. This is because of the linear fit used to estimate H, which heavily depends on the region from where the samples are chosen. This is unlike the R/S

or the variance time test where there are relatively very few samples available for the linear fit. For encodings with rate control, we find that H values estimated from the R/S plots, are quite different from that of variance time plots where both indicate that there is hardly any long range dependence.

Some logscale diagrams are given in Figure 10. We observe that the logscale diagrams give, in many cases, H estimates very close to one or above one, which should be viewed with caution. The H estimates around and above one appear to be due to the fact that the employed logscale estimation assumes Gaussian time series, whereas our trace data is typically non-Gaussian.

The logscale diagrams in Figure 10 typically exhibit a "knee" around scale $j = 4$ or $j = 5$. This time scale, which corresponds to roughly 16 to 32 frames (i.e., about half a second to one second of video) may be a transition point from short-term to long-term scaling. For the longer scales, the logscale plots indicate a reasonable level of scaling, with some "bumps" for very large scales. We find the same logscale behavior in the single layer encoding statistics given in table 4 of Part2 of the technical report series.

We observe that the normalized form $\underline{c}_f$ tends to be very large for video encodings with logscale $H < 0$. We further observe that as the quality of the encoding decreases, the $\underline{c}_f$ estimation either tends to decrease (*Silence of the Lambs*) or remains nearly unchanged (*LectureHQ-Reisslein*).

Table 4: Hurst parameters estimated from variance time plot, scaling parameters estimated from logscale diagram for base layer traffic.

Table 5 gives the scaling parameters α_q for the orders $q = 0.5$, 1, 1.5, 2, 2.5, 3, 3.5, and 4. Figures 11 and 12 give the multiscale diagrams and the linear multiscale diagrams. It can be observed that the scaling parameters increase with increasing q with the exception of the scaling parameters which are negative (in such a case, the scaling parameter decreases as q increases, see *ParkingLot*). With the decrease in the quality of encoding of a given video sequence, the scaling parameter tends to be oscillatory. The Hurst parameter estimate is given by $H = \alpha_2/2$. We observe from Table 5 that in some cases the H estimate is larger than 1, this is because multiscale estimation assumes a Gaussian time series, whereas the traces are typically non-Gaussian. In summary from the R/S, periodogram, variance test, logscale and multiscale Hurst parameter estimates we can conclude that for video encodings without rate control the *ParkingLot* sequence does not exhibit any long range dependence and *Silence of the Lambs* exhibits the strongest long range dependence. For rate control encodings with 128 kbps and 256 kbps, none exhibits long range dependence, whereas some videos at 64 kbps do exhibit weak long range dependence. This is because rate control at 64 kbps is not effective in some cases and can be visualized as a low quality encoding.

2.2 Enhancement Layer Traffic

Table 6 gives the mean frame size $\bar{X}^e$, the coefficient of variation CoV_X^e, and the peak-to-mean ratio $X^e_{\max}/\bar{X}^e$ of the enhancement layer frame sizes along with the mean bit rate $\bar{X}^e/T$ and the peak bit rate $X^e_{\max}/T$.

Focusing for now on the encodings without rate control, as the quantization parameter increases (quality of encoding decreases) we find that the enhancement layer mean frame size decreases, except for the H.M.Q quality encoding where all video encodings (with the exception of *Snowboard with Commercials*) give a larger mean frame size than the 060810.Q encodings. Further investigation of this effect is needed. We further observe that the average enhancement layer frame sizes are 2 to 3 times larger than the corresponding average base layer frame sizes for videos encoded without rate control. Since the enhancement layer increases the format of the decoded frame by a factor of four, we would expect that the enhancement layer is an average of roughly three times larger than the base layer. However there is no consistent behavior in this ratio as the quality of the encoding changes for a given video.

We also observe that for most of the encodings, the enhancement layer traffic is smoother (CoV_X^e is small for smooth traffic) than the base layer traffic with exception of a few. This effect is especially significant for the medium and low quality encodings. It is also observed that the CoV_X^e varies over a narrower range as compared to the variation of the CoV_X^b for different encodings. The peak to mean ratio ($\bar{X}^e/\bar{X}^b$) is 1 to 1.5 times larger than the corresponding $X^b_{\max}/\bar{X}^b$. The CoV_X^e and $\bar{X}^e/\bar{X}^b$ generally increase a little bit as the quality of the encoding decreases indicating the fact that low quality encoded video traffic tends to be more bursty. The combined effect of the reduced variability and increased average of the enhancement layer traffic on providers of scalable video services over networks will be studied in detail in future work.

We next turn to the enhancement layer frame size statistics for the encodings with rate control. Recall from Part 1 that the rate control is applied only to the base layer. The enhancement layer is encoded with the fixed quantization parameters 10 for I frames, 14 for P frames, and 16 for B frames, which we refer to as the medium quality level. Indeed, the frame size statistics of the enhancement layer of the rate controlled encodings are roughly equal to the corresponding statistics of the medium quality encodings without rate control. It is also interesting to note that these enhancement layers, which are encoded without rate control are significantly smoother than the base layers, which are encoded with rate control (albeit with a scheme that strives to provide rate control at the GoP time scale).

We remind here again that the enhancement layer is not rate controlled, rate control is applied only for base layer. This is the reason why we do not see a constant frame size in

enhancement layer for rate controlled encodings. For a given encoding mode, *Silence of the Lambs* has the smallest mean frame size in the enhancement layer and *ParkingLot* has the largest mean frame size. For encodings ranging from the high quality to the H.M quality, we observe that the mean frame size of *Oprah w/o Commercials* is larger than for *Terminator I*, but from the medium quality onwards this reverses. When compared to the corresponding base layer mean frame size, *Silence of the lambs* has the smallest mean frame size, *ParkingLot* has the largest frame size in encodings without rate control and 64 kbps target bit rate control encoding.

We observe that the mean frame size in the enhancement layer varies slightly. This indicates that the amount of traffic generated in the enhancement layer is effected by the base layer encoding type and quality. This is because the larger the target bit rate at the base layer, the more information the video captures in the base layer, leaving less information for the enhancement layer.

Table 6: Overview of frame statistics of the enhancement layer of spatial scalable encoded video

Table 7 gives the mean GoP sizes ($\bar{Y}^e$), the coefficients of variation of the GoP sizes (CoV_Y^e), and the peak-to-mean ratio ($Y_{\max}^e/\bar{Y}^e$) of the GoP sizes, as well as the peak bit rate ($Y_{\max}^b/(GT)$).

We observe that the CoV_Y^e and $Y_{\max}^e/\bar{Y}^e$ of video sequences encoded without rate control have slightly higher values (around 10 to 30 percent) when compared with the corresponding values for base layer traffic given in Table 2, in some encodings they are nearly equal. As the quality of the encoding decreases, the CoV_Y^e and $Y_{\max}^e/\bar{Y}^e$ values generally increases indicating that low quality video is bursty in nature. For rate controlled encodings, we find that the CoV_Y^e and $Y_{\max}^e/\bar{Y}^e$ are almost equal for target bit rates of 64, 128, and 256 kbps and are little bit higher when compared with the corresponding CoV_Y^b and $Y_{\max}^b/\bar{Y}^b$. This is because the enhancement layer traffic is not rate controlled (rate control is applied only for base layer) and the fact that MPEG trys to maintain a constant quality at variable traffic. The GoP statistics for encodings with the target bit rates 64, 128, and 256 kbps have similar values with very slight changes because we encoded the enhancement layer with Medium Quality (I=10, P=14, B=16). Slight changes in values are because the type of encoding in base layer effects enhancement layer traffic.

As per general expectation the mean GoP size ($\bar{Y}^e$) in the enhancement layer is quite large (roughly 3 times) when compared to the base layer mean GoP frame size ($\bar{Y}^b$) because the enhancement layer is encoded in the CIF format (where the CIF frame format is 4 times larger than the QCIF frame format).

Figure 13 gives the frame size X_n^e (in byte) as a function of the frame number n. From the plots we observe that *Oprah w/o Commercials* has the least variability, whereas *Snowboard with Commercials* and *Silence of the Lambs* both have higher variability (black regions in the plot indicate high density of samples and the wider the black region is, the wider the samples are distributed). Comparing Figure 13 and Figure 1 (*Oprah w/o Commercials*), we clearly notice the increase in the peak-to-mean ratio in the enhancement layer traffic as the mean of the plots remains almost constant, however the peaks are higher in the enhancement layer traffic. Similar behavior is observed for *Snowboard with Commercials*. Plots b and e of Figure 13 look similar, as the 128 kbps target bit rate has enhancement layer set to the medium quality level. The other two plots (d and f) should look similar to the corresponding medium quality encodings.

Figure 14 gives the GoP size Y_m^e (in bytes) as a function of the GoP number m. For encodings without rate control these plots look similar to corresponding GoP plots for the base layer traffic. This is corroborated by the fact that the coefficients of variation for the base layer and the enhancement layer (GoP level) have nearly the same values and peak-to-mean ratios are close as reported in Table 2 and 7. As the enhancement layer is encoded in Medium quality, we observe that the plots d,e, and f (which are encoded at the target bit rates 64, 128, and 256 kbps) are similar to the GoP level enhancement layer traffic plot for videos encoded without rate control at Medium quality.

The observations and conclusions made from Figure 13 and Figure 14 are further strengthened by Figure 15 which gives the histograms of the frame sizes X_n^e. The wider the histogram, the higher is variance of the traffic. Similar to earlier observations, the encodings with rate control have almost the same histograms as one would obtain from the corresponding enhancement layer of Medium quality encoded videos.

Figure 16 gives the autocorrelation coefficient $\rho_X^e(k)$ of the frame size sequence $X_n^e,\ n = 0, \ldots, N-1$, as a function of the lag k (in frames). We observe that the autocorrelation function, is a series of spikes superimposed on a decreasing slope curve. High magnitude spikes are due to relatively large sizes of P frames in a GoP as compared to B frames. The frequency of these large magnitude spikes is a 12 frame lag, corresponding to the P frame frequency in the enhancement layer. However, in this plots we do not observe intermediate spikes as was observed in single layer autocorrelation function plots. In addition, we find that the relative difference between the maximum and minimum value of the spikes is smaller than what is found in the corresponding single layer autocorrelation function. This is because of the GoP structure difference (single layer has I frames which are far larger than P and B frames, thus we find a large spike followed by a few smaller spikes due to P-P and B-B correlation). We

further notice that unlike the previous autocorrelation plots observed for base layer and single layer traffic, the autocorrelation plots in the enhancement layer tend to be smooth in between spikes (for Medium and Low quality). This is because there are only P and B frames in the enhancement layer and inside a GoP, many a times B frames can be of almost same sizes. This leads to near exponential decay in between spikes (because autocorrelation of step function and another step function is a exponential decay).

We further notice that for rate controlled sequences, the autocorrelation plot is similar to the ones for Medium quality encodings without rate control. Figure 17 gives the autocorrelation coefficient $\rho_{Y^e}(k)$ of the GoP size sequence $Y^e_m,\ m = 0, \ldots, N/G - 1$, as a function of the lag k (in GoPs). We find near exponential decay for *Snowboard with Comm* and *Oprah w/o Comm*, the former taking 40 GoP duration and the latter taking 80 GoP duration to drop to zero. This might indicate a weak long range dependence. We also observe that for videos encoded without rate control, the GoP size autocorrelation for enhancement layer is similar to the one obtained for base layer traffic except for a level shift in the enhancement layer and we found the same difference for encodings with rate control.

Table 8 gives the Hurst parameter obtained with the R/S heuristics and the periodogram for $X^e_n,\ n = 0, \ldots, N - 1$, as a function of the aggregation level a and Figure 19, and Figure 20 gives the corresponding plots. It is found that the Hurst parameter estimates from the R/S plot and the periodogram for the enhancement layer traffic are almost the same as the one obtained for base layer traffic considering encodings of similar quality (without rate control) with the exception of only one video, namely the *ParkingLot* at 060810 quality encoding. This again indicates that the long range dependence property of a video sequence does not change with scaling. For CIF spatial encodings, we choose the base layer to be in the QCIF format (which is a scaled down version of CIF sequence) whereas the enhancement layer in the CIF format. This is because scaling changes the encoded frame size, but it does not effect the successive frame size relation (relative) which means that autocorrelation function slope is relatively unchanged, thus not effecting the long range dependence estimation (compare Figure 17 for enhancement layer GoP level autocorrelation function and Figure 6 for base layer GoP level autocorrelation function).

The observations made for Hurst parameter estimation given in Table 3 for encodings without rate control are also valid for Table 8, as the H estimation in the enhancement layer is nearly equal to that of the base layer traffic.

For encodings with rate control, as the enhancement layer is encoded with Medium quality (rate control is applied for only base layer) we observe that the H estimate differs from that of Table 3. These new value of H estimation is equal to that obtained for Medium quality

encodings of enhancement layer and all three encoding types 64, 128, 256 kbps show little variation in the H estimates (this little change is because rate control is applied to the base layer) but they do not effect the final decision about the long range dependence from the H parameter.

Table 8: Hurst parameters estimated from pox diagram of R/S and periodogram as a function of the aggregation level a for enhancement layer traffic.

Table 9 gives the Hurst parameter estimated using the variance time plot as well as the scaling parameters c_f and α (also expressed as $H = (1+\alpha)/2$) estimated from the logscale diagram. With the exception of *ParkingLot* encoding at 060810 quality all H estimates obtained from the variance time plots tend to be nearly equal to the ones obtained for corresponding base layer traffic. The rate controlled sequences have similar H estimate from variance time plots (Figures 18) as they all are encoded with Medium quality and hence we find these values to be equal to Medium quality values (of enhancement layer). There is considerable difference in the H estimate obtained from logscale diagrams. Most of the estimates are greater than one, because of non-Gaussian traffic. It is quite interesting to note that *ParkingLot* exhibits long range dependence for large a.

Comparing the enhancement layer traffic logscale plots (Figure 21) with that of the base layer traffic (Figure 10) we find that *Silence of the Lambs* and *Oprah w/o Comm* show similar behavior whereas *Snowboard with Comm* shows a different behavior (for encodings without rate control). For encodings with rate control we find the logscale plots to be similar to the corresponding medium quality enhancement layer logscale plots.

As the quality of encoding decreases, we find normalized form $\underline{c}_f$ to decrease.

Table 9: Hurst parameters estimated from variance time plot, scaling parameters estimated from logscale diagram for enhancement layer traffic.

Table 10 gives the scaling parameters α_q for the orders $q = 0.5$, 1, 1.5, 2, 2.5, 3, 3.5, and 4. As was observed before, the scaling parameters increase with increasing q. The Hurst parameter estimates obtained from the multiscale diagram (Figures 22) for the enhancement layer are in many cases quite different, but we find some encodings which still behave alike in enhancement layer but there is no consistent trend in the behavior. *ParkingLot* encoded with High quality gives $H = 0.9$ indicating long range dependence, whereas for all other quality levels it does not show long range behavior. Multiscale parameters are alike for 64, 128, and 256 kbps target bit rate encodings. Figure 23 gives linear multiscale diagrams.

Table 10: Scaling parameters estimated from multiscale diagram for enhancement layer traffic.

2.3 Aggregated Traffic and Correlation between Base and Enhancement Layer Traffic

In this section we investigate the aggregate (base + enhancement layer) traffic and the correlation between the base layer and the enhancement layer traffic of spatial scalable encoded video. We estimate the covariance between base layer and enhancement layer at the frame level as

$$S_{be} = \frac{1}{N-1} \sum_{n=0}^{N-1} (X_n^b - \bar{X})(X_n^e - \bar{X}^e), \tag{1}$$

and the base-enhancement layer correlation coefficient as

$$\rho_{be} = \frac{S_{be}}{S_X^b \cdot S_X^e}. \tag{2}$$

Similarly, we estimate the covariance between base layer and enhancement layer at the GoP level as

$$S_{be}^{(G)} = \frac{1}{N/G-1} \sum_{m=0}^{N/G-1} (Y_m^b - \bar{Y}^b)(Y_m^e - \bar{Y}^e), \tag{3}$$

and the corresponding correlation coefficient as

$$\rho_{be}^{(G)} = \frac{S_{be}^{(G)}}{S_Y^b \cdot S_Y^e}. \tag{4}$$

We also investigate the characteristics of the aggregate traffic at the frame time scale $X_n = X_n^b + X_n^e,\ n = 0, \ldots, N-1$, and the GoP time scale $Y_m = Y_m^b + Y_m^e,\ m = 0, \ldots, N/G-1$. The compression ratio, mean frame size $\bar{X}$, the coefficient of variation CoV_X, the peak-to-mean ratio $X_{\max}/\bar{X}$, along with the bit rates and the base-enhancement layer correlation coefficient ρ_{be} are reported in Table 11. Table 12 gives the corresponding statistics for single layer encodings.

For the videos encoded without rate control, we observe that the $X_{\max}/\bar{X}$ of the aggregated frame sizes increase as the quality of the encoded video decreases, lowest quality encodings exhibiting highest ratios. The coefficient of variation CoV_X has a double "hump". The peaks are located at 060810.Q and medium quality (corresponding to 101416 QP). We observed the same behavior of peak-to-mean ratio and coefficient of variation in single layer CIF encodings without rate control as discussed in Part2 of this technical report series.

For sequences encoded with rate control, we observe that CoV_X and $X_{\max}/\bar{X}$ decrease as the target bit rate increases, with the exception of *ParkingLot* sequence where the peak-to-mean ratio increases as the target bit rate increases.

Comparing the average frame size of various video sequences encoded without rate control for spatial scalable and single layer encodings we do not observe a consistent trend. However, we observe that spatial scalable encodings at high quality have larger frame sizes than their single layer counterparts (usually 14 to 33 percent larger). For low quality encodings we observe that the average frame sizes in spatial encodings are 5 to 30 percent smaller than that of the corresponding single layer encodings. For medium quality encodings we observe that in most cases, the spatial encodings have smaller average frame sizes when compared to single layer encodings. For rate control encodings (64, 128, and 256 kbps) we observe that spatial encodings have always higher average frame size than the single layer encodings (at these target bit rates rate control is not effective) this can range from 20 to 100 percent.

We observe that the base-enhancement layer correlation coefficient can be used to show how well matched the sizes of the base and enhancement layers are for a given encoding mode. For the high quality encoding of *Oprah without Comm* without rate control, the enhancement and base layers are more strongly correlated than they are for the medium and low quality encodings without rate control. This indicates that the sizes of the frames in the base and enhancement layers are closer in size for the high quality encodings than for the medium or low quality encodings. Similar observations can be made for other video sequence such as *LectureHQ-Reisslein* but for different quality levels.

Video sequences such as *Silence of the Lambs* and *Terminator I* give very small base-enhancement layer coefficients for all quality levels (without rate control) indicating that the base and enhancement layers frame sizes are not very closely related. As expected the base-enhancement layer coefficient is never negative for the listed encodings.

Table 11: Overview of frame-level statistics of aggregated spatial scalable video traffic

Table 13 gives the mean GoP size ($\bar{Y}$), the GoP coefficient of variation (CoV_Y), the GoP peak-to-mean ratio ($Y_{\max}/\bar{Y}$), along with the peak bit rate ($Y_{\max}/(GT)$) and the GoP level base-enhancement layer correlation coefficient (ρ_{be}^G). The observations made earlier for Table 11 can be extended here with a few exceptions.

We observe the that CoV_Y exhibits a hump which is centered somewhere near the medium quality as was observed in other tables. The CoV_Y and $Y_{\max}/(GT)$ are smaller than corresponding CoV_X and $X_{\max}/(GT)$ because of the aggregation.

We observe that the base-enhancement layer coefficient is always high at the GoP aggregation level in all the video sequences for encodings without rate control indicating a strong base GoP size and enhancement layer GoP size correlation. We further observe that for encodings with rate control, this correlation is very small and even negative for a target bit rate of 256 kbps (actually correlation decreases with increasing target bit rate). This is because the base layer is encoded in QCIF format with rate control being very effective at 128 kbps and 256 kbps whereas enhancement layer is encoded without rate control. This leads to a lower base-enhancement layer correlations.

Table 13: Overview of GoP–level statistics of aggregated spatial scalable video traffic

		GoP Size			Bit Rate	Corr.

3 Analysis of Video Quality

In this section we study the video quality of the base layer stream and the aggregate (base + enhancement layer) stream. This quality analysis focuses on the quality of the luminance component.

3.1 Base Layer Quality

We first consider the base layer. Recall that $Q_n^{b,Y},\ n = 0, \ldots, N-1$, denotes the PSNR quality (in dB) of the luminance component in frame n. For convenience, we write Q_n^b for $Q_n^{b,Y}$, and M_n^b for the corresponding MSE quality, i.e., $M_n^b = p^2/(10^{(Q_n/10)})$.

Table 14 gives the average quality ($\bar{Q}^b$), the coefficient of quality variation ($CoQV^b$), and the quality range ($Q_{\min}^{\max,b}$) for the decoded base layer stream. The quality statistics are provided for the frame level and the GoP level. In spatial encodings, the base layer is obtained by spatially down-sampling the CIF video sequence (which is the input) hence we observe that base layer frame have lower average quality than their corresponding QCIF single layer encodings.

We observe that in base layer encodings, the mean frame quality $\bar{Q}^b$ does not change as much with changing quantization scale as would be observed in single layer QCIF encodings. This is because already the source base layer video is of low quality (due to downsampling). We observe that *ParkingLot* sequence has very low base quality as the source video sequence was of low quality.

The coefficient of quality variation $CoQV^b$ increases as the quality of encoding decreases however this increase is very small. The alternate coefficient of quality variation $CoQV'^b$ decreases as the quality of encoding decreases. We observe similar behavior for the GoP level also.

Table 14: Overview of quality statistics of base layer of spatial scalable encoded video

		Frame Level				GoP level		
Enc. M.	Video	$\bar{Q}^b$	$CoQV^b$	$CoQV'^b$	$Q_{\min}^{\max,b}$	$CoQV^{(G),b}$	$CoQV'^{(G),b}$	$Q_{\min}^{\max,(G),b}$

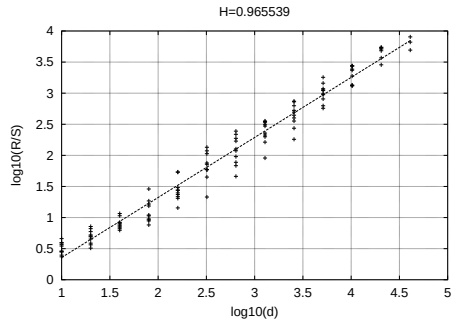
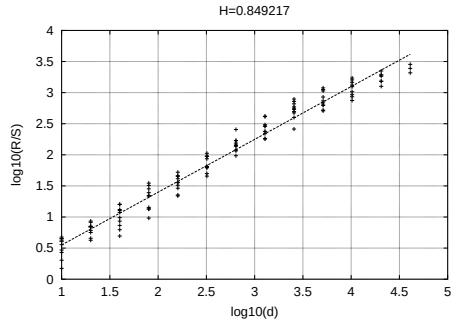
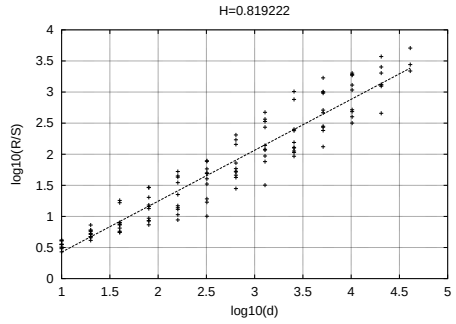
Figure 24 gives the video frame qualities Q_n^b (in dB) as a function of the frame number n. Its quite interesting to observe that encodings with and without rate control for a given video sequence shows a very similar quality variation pattern in the plot. However looking at the values we notice that there is a small difference between different quality encodings.



a) *Silence of the Lambs* with high quality

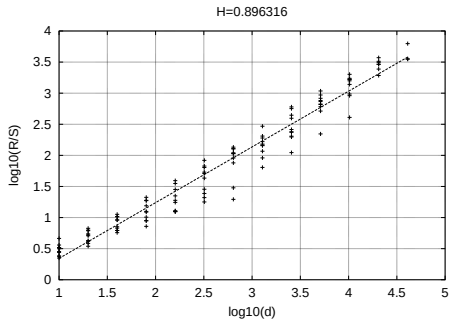


b) *Snowboard with Comm* with medium quality

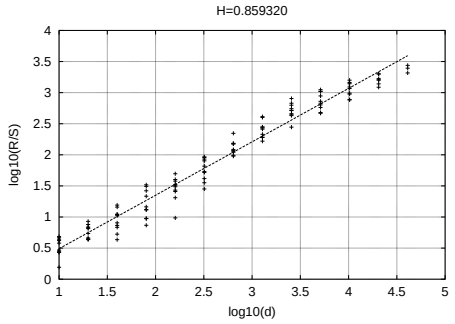


c) *Oprah w/o Comm* with low quality

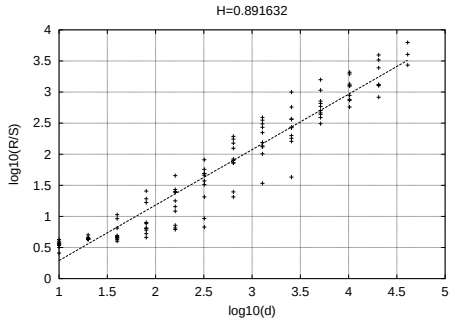
Encoding without rate control



d) *Silence of the Lambs* with 256 kbps target bit rate



e) *Snowboard with Comm* with 128 kbps target bit rate



f) *Oprah w/o Comm* with 64 kbps target bit rate

Encoding with rate control

c) *Oprah w/o Comm* with low quality

Figure 25 gives the histogram of the frame qualities Q_n^b. For different quality encodings of the same video sequence we notice that the quality distribution function look alike with some minor differences. This is unlike QCIF single layer encoding frame quality distribution plots given in Part2 of the technical report series. This fact is also corroborated by the fact that coefficient of variation (base layer quality) and mean frame quality changes very little with changing quality of encodings.

Figure 26 gives the MSE autocorrelation coefficient $\rho_M(k)$ as a function of lag k (in frames). For high quality encodings we observe a chain of spikes superimposed on a decreasing slope curve. These spikes are due to high quality I frames as compared to P and B frames. These spikes occur periodically at 12 frame period corresponding to the frequency of I frames. As the quality of encoding decreases this difference in quality between I, P, and B frames decreases, hence we find near smooth curve for low quality encodings. As the frame quality behavior is alike for rate control sequences also, we find the autocorrelation functions also to be similar. Figure 27 gives the MSE autocorrelation coefficient $\rho_M^{(G)}(k)$ as a function of lag k (in GoPs). These tend to be smoother as the mean square error is averaged over a GoP now.

3.2 Quality of Aggregate Video Stream

We now proceed to study the quality of the aggregate stream. Recall that $Q_n^{e,Y},\ n = 0, \ldots, N-1$, denotes the improvement in the PSNR quality (in dB) of the luminance component in frame n, achieved by adding the enhancement layer. We denote $Q_n^{\text{agg}},\ n = 0, \ldots, N-1$, for the PSNR quality (in dB) of the luminance component in the decoded aggregate stream. By definition, $Q_n^{\text{agg}} = Q_n^b + Q_n^e,\ n = 0, \ldots, N-1$. We denote $M_n^{\text{agg}},\ n = 0, \ldots, N-1$, for the corresponding MSE quality.

Table 15 gives the average quality $\bar{Q}^{agg}$, the coefficient of quality variation $CoQV^{\text{agg}}$, the quality range $Q_{\min}^{\max,agg}$ for the decoded base layer stream. The quality statistics are provided for the frame-level and the GoP-level. Table 16 gives the corresponding statistics for single layer encodings.

We observe that spatial scalable encoding gives somewhat lower quality frame (on an average 1 dB) when compared to the corresponding single layer encoding frame quality. This difference is however very small for high quality encodings. In some cases this can be as low as 3 dB (*ParkingLot* and *LectureHQ-Reisslein* at 101010 quality encoding). Average frame quality can degrade upto 7dB when we change the encoding from high quality to low quality.

When comparing the CIF single layer encoding frame size with the aggregated CIF spatially encoded frame size, one has to be careful. In order to have a fair comparison, we need to see that both of them (single and spatial) achieve approximately the same quality. For example *Oprah*

w/o Commercials gives an average quality of 36.10 dB (at H.Q. corresponding to 040404)), which is closest to single layer 040404 quality encoding which gives 36.24 dB. When we consider the mean frame size, then we see that spatial encoding has 22.42 KB whereas single layer has 19.27 KB (which corresponds to 16.33 percent overhead in framesize).

The coefficient of quality variation decreases with decreasing quality of encoding, whereas the alternative coefficient of quality variation increases with decreasing quality of encoding. For GoP aggregation level, we find that $CoQV^{(G),agg}$ and $CoQV'^{(G),agg}$ are roughly same as was obtained for frame level.

Table 15: Overview of quality statistics of aggregated layer of spatial scalable encoded video

		Frame Level				GoP level

Figure 28 gives the video frame qualities Q_n^{agg} (in dB) as a function of the frame number n.

Unlike the base layer plots, these plots show a difference in quality variation for rate controlled and non rate controlled encodings. This is because rate control is only applied to the base layer, whereas the enhancement layer is fixed at medium quality. In encodings without rate control both base and enhancement layer have the same quality parameters. However, when we compare the same video sequence without rate control at different quality levels, we find that the quality variation plots are similar.

Figure 29 gives the histogram of the frame qualities Q_n^{agg}. In most of the high quality encoding without rate control plots we observe double peaks (usually a small peak at very high quality). This is because of the high quality I frames which constitute around 8.3 percent of total frames. This small peak vanishes as the quality of encoding decreases (because of the decreasing gap between between I frame quality and the P and B frame quality).

Figure 30 gives the MSE autocorrelation coefficient $\rho_M(k)$ as a function of lag k (in frames) and Figure 27 gives the MSE autocorrelation coefficient $\rho_M^{(G)}(k)$ as a function of lag k (in GoPs). We find similar observations as was reported in Figure 26 and Figure 27.

4 Correlation between Frame Sizes and Qualities

Table 17 gives the correlation coefficients between quality and the frame size, both for the base layer and the aggregate stream. Both the MSE quality to frame size correlation (ρ_{XM}) and the PSNR quality to frame size correlation (ρ_{XQ}) are provided, both for the frame level and the GoP aggregation level.

We notice that correlation coefficients ρ_{XQ} for base layer traffic is negative for all encodings including rate control. For the aggregated stream we find that ρ_{XQ} is negative in most cases except for *LectureHQ-Reisslein* and *ParkingLot* sequences encoded at the high, 040608, and 060810 quality levels. We find these values are more negative at the H.M quality level compared to other encodings and quality levels for aggregated stream traffic. When compared to the base layer traffic correlation coefficients, we find these values are a little bit more negative for the aggregated traffic in most cases, this is because of the fact that when we take into consideration the aggregated stream which is formed by adding enhancement layer (CIF which is nearly 3 times larger) to the base layer (QCIF). This aggregated stream however increases by nearly a factor of 4 but its quality does not change that much. Hence we find that (X,Q) plots tends to show a more negative slope and hence more negative correlation coefficients. When compared to single layer CIF encodings, we find that ρ_{XQ} is positive for all of the sequences encoded at 040608 quality level and the values tend to be lesser negative than there spatial counterparts for other encodings.

Table 17: Correlation between quality and traffic for spatial scalable traces

		Base Layer				Aggregate Stream			
		Frame Level		GoP level		Frame Level		GoP level

Figures 32 and 33 give scatter plots of the tuples $(X_n,\ Q_n)$ and $(X_n^{(12)},\ Q_n^{(12)})$, respectively. For high quality *Silence of the Lambs* spatial encoded video, we find that most of the frames are in the range of 36-40 dB. For medium quality *Snowboard with Commercials* we notice a wider range of quality variation however now over a smaller frame sizes (because of the reduced quality level). This quality variation range is highest for low quality encoding of *Oprah without Commercials*.

For rate controlled sequence we notice that frame size quality tuples are concentrated over a smaller frame size range with a wide variation in quality levels (as was mentioned in earlier technical reports, rate control tries to achieve constant bit rate by varying frame quality) even though rate control is not effective for target bit rates of 64, 128, and 256 kbps.

Figure 34 gives the rate-distortion plots, i.e., the average video quality ($\bar{Q}$) as a function of the mean bit rate. The plots are obtained from the five different quality level encodings of the videos. The main point which should be observed here is that rate distortion plots do not have the same slope for different video sequences. The slope is not the same for base and enhancement layer for a given sequence encoded at a given encoding without rate control.

5 Conclusions

From the preceding analysis of the base layer, the enhancement layer, and the aggregated layer traffic, we observe a double hump in the coefficient of variation and peak-to-mean ratio centered at the 060810.Q and the medium quality level. This means that the video traffic at a particular quality level cannot be simulated by simply scaling the video traffic at other quality levels. This double hump in the CoV_X and the $X_{\max}/\bar{X}$ is to the best of our knowledge a new insight. For single layer encodings in the CIF format, the coefficient of variation exhibits double hump. However, single layer encodings in QCIF format exhibit only a single hump.

The long range dependence properties appear to be consistently strong for all quality levels of the videos encoded without rate control. In most of the cases, the Hurst parameter estimated from the R/S plot, the periodogram, and the variance time plot are the same for the base layer traffic and the enhancement layer traffic. This indicates that long range dependence is not changed by scaling the input video.

Most importantly, our traces of spatial scalable encoded videos provide realistic traffic data for evaluating the widely advocated networking scenario with a (nearly at 128kbps, and 256kbps) constant bit rate base layer and a variable bit rate enhancement layer. The widely used TM5 rate control mechanism, which we also employed in our encodings, tries to stabilize the bit rate at the GoP time scale (while the bit rate at the frame time scale is quite variable). We therefore recommend to employ our traces in scenarios were the video traffic is smoothed

over the individual frames in a GoP.
